(Dated: February 2, 2008)

We have studied the resonance fluorescence of a room-temperature rubidium vapor excited to the atomic $^5P_{3/2}$ state (D_2 line) by powerful single-frequency cw laser radiation (1.25 W/cm^2) in the presence of a magnetic field. In these studies, the slow, linear scanning of the laser frequency across the hyperfine transitions of the D_2 line is combined with a fast linear scanning of the applied magnetic field, which allows us to record frequency-dependent Hanle resonances from all the groups of hyperfine transitions including V- and Λ - type systems. Rate equations were used to simulate fluorescence signals for ^{85}Rb due to circularly polarized exciting laser radiation with different mean frequency values and laser intensity values. The simulation shows a dependence of the fluorescence on the magnetic field. The Doppler effect was taken into account by averaging the calculated signals over different velocity groups. Theoretical calculations give a width of the signal peak in good agreement with experiment.

I. INTRODUCTION

Sustained interest in resonant magneto-optical effects in atomic vapors is due to their importance to fundamental physics but also to possibility of using these effects in numerous applications (see [1, 2, 3, 4] and references therein). Besides the obvious dependence on the applied magnetic field, the resonant nature of these effects implies a substantial dependence on the laser frequency. Meanwhile, as a rule, only one or two of these parameters is varied in a given experimental measurement. In the present work, we report the results of an investigation of the nonlinear Hanle effect [5, 6] where both the laser frequency and the magnetic field were scanned continuously and simultaneously at different sequence rates [7]. This technique enables us to acquire additional information in one measurement sequence, and can help to better understand and model the processes under study. This technique can be applied to other magneto-optical effects as well [8].

Usually, models of nonlinear magneto-optical effects are based on the optical Bloch equations [9]. At the same time, as was shown in [10], simpler rate equations for Zeeman coherences for stationary or quasi-stationary excitation are equivalent to the optical Bloch equations. The model based on the rate equations was successfully applied to studies of atomic interactions with laser radiation in cells in the presence of an external magnetic field [5, 6, 11].

The elaboration of a realistic model of the interaction of alkali atoms with laser radiation is complicated by the fact that the fine structure levels of a typical alkali atom consists of several hyperfine structure (HFS) levels that in experiments in cells can be only partially resolved spectroscopically due to Doppler broadening. If an external magnetic field is applied, the situation becomes

even more complicated. The magnetic field mixes together magnetic sublevels with the same magnetic quantum number M , but belonging to different hyperfine states. This mixing can be quite strong, as was shown experimentally and confirmed in a model for Rb atoms [12] confined in an extremely thin cell [13]. In that study the extremely thin cell allowed to resolve spectroscopically transitions between specific magnetic sublevels. When scanning the laser frequency there appeared in a fluorescence excitation spectrum transitions that would not be allowed in the absence of the level mixing due to magnetic field.

In the present study we propose to show that in the model of the nonlinear Hanle effect we have for the first time accounted *simultaneously* for all these effects, namely, the creation of Zeeman coherences between magnetic sublevels in the ground and excited states, the mixing of the different hyperfine levels in the magnetic field (partial decoupling of the electronic angular momentum of the electrons from the nuclear spin), and the Doppler effect in the manifold of magnetic sublevels of all hyperfine levels of the fine structure states involved.

II. EXPERIMENT

A. Experimental details

A schematic drawing of the experimental setup is shown in Fig. 1. A radiation beam from the solitary laser diode (SanyoTM DL-7140-201 W) was directed into the 1 cm-long glass cell containing natural rubidium. The temperature of the cell was $T_{\text{cell}} = 24 \text{ C}$ ($N_{\text{Rb}} = 8.6 \times 10^9 \text{ cm}^{-3}$). The measured output power was 45 mW at the Rb D_2 line, the spectral linewidth was $\sim 15 \text{ MHz}$, and the laser beam diameter was 1.5 mm. The cell was placed

FIG. 1: Experimental Setup. Abbreviations: L- laser, BS- beam splitter, AT- attenuator, P- polarizer, L4- $\lambda/4$ plate, Rb - Rubidium cell in Helmholtz coils, FI- fluorescence detector, PD- photodiode, M- 100 % mirror, Ref- reference Rb cell, G- generator / booster, A_{in} - analog in, A_{out} - analog out.

in 3 mutually orthogonal pairs of Helmholtz coils without metal shielding, which reduced the dc magnetic field to ~ 10 mG and could apply a magnetic field of up to 80 G in a chosen direction. The resonant fluorescence emerging from the cell was detected by a photodiode placed at an angle of 90 degrees to the laser beam, 14 cm from the cell. The detection solid angle was 0.004 sr. The total intensity of the laser induced fluorescence was measured without spectral or polarization selection. It was possible to simultaneously record also the transmitted signal and the saturated absorption signal (branched to an auxiliary setup, as shown in Fig. 1). Control of the diode laser injection current and hence, the radiation frequency, as well as data acquisition were done by means of virtual function generator and a multi-channel oscilloscope, with the help of a National InstrumentsTM DAQ board installed in the PC. The software was written in LabVIEWTM. The measurements were performed by linearly scanning the laser frequency over a 6 GHz range around the Rb D_2 line, covering the ^{87}Rb $F_g = 2 \rightarrow F_e = 1, 2, 3$, ^{85}Rb $F_g = 3 \rightarrow F_e = 2, 3, 4$, and ^{85}Rb $F_g = 2 \rightarrow F_e = 1, 2, 3$ Doppler-broadened and partially overlapping transitions. The typical duration of a one-way scan was 5 s. Within this time period, the magnetic field is periodically scanned by 120 triangular bipolar pulses, each with a duration of 41.5 ms. The number of measurement points per frequency scan was 50000 (over 400 points per magnetic field scan). The fluorescence measurement in one scanning point takes 100 μs . This measurement time interval is sufficiently large to allow good signal resolution and the development of a steady state interaction regime. The mutual orientation of the laser radiation, its polarization, and the direction of the magnetic field is shown in Fig. 2.

FIG. 3: Fluorescence signal for circularly polarized excitation light when simultaneously scanning the mean frequency $\bar{\omega}$ of the laser light and the magnetic field B.

B. Experimental Results

Figure 3 shows the *double-scanning* fluorescence excitation spectra for the circularly polarized excitation recorded with laser intensity $I_L = 1.25 \text{ W/cm}^2$. We can clearly see fluorescence coming from the excitation of ^{87}Rb atoms in the ground state level $F_g = 2$, as well as fluorescence coming from the excitation of ^{85}Rb atoms in the ground state levels $F_g = 3$ and $F_g = 2$. Vertical lines in the graph show frequencies of atomic transitions for atoms at rest. For example, line "3-4" shows the position of the transition $F_g = 3 \rightarrow F_e = 4$ for ^{85}Rb atoms. In this figure it can be seen that the structure of the nonlinear Hanle signal depends on ground state HFS level from which it was excited. The Hanle signals for excitation from the ^{87}Rb $F_g = 2$ and from the ^{85}Rb $F_g = 3$ levels exhibit sharp, high-contrast peaks in the vicinity of zero magnetic field. The inset in Fig. 3 shows the dependance of the fluorescence on the magnetic field in the vicinity of these peaks. The width of these high-contrast peaks is about 2 G. In contrast, the fluorescence excited from the ground state HFS level $F_g = 2$ of ^{85}Rb exhibits dips in the vicinity of zero magnetic field of approximately the same width as the previously discussed

peaks. For each of the three Doppler-overlapped groups of the three HFS transitions, sub-Doppler dips appear at high laser intensity, located at the frequency positions of the two crossover resonances linked by the cycling transitions. As was shown (but not comprehensively explained) in [14], these dips arise even if precautions are taken to eliminate the backward-reflected beam from the cell, as was done also in this work.

Similar spectra to the double-scanning fluorescence excitation spectra depicted in Fig. 3 were taken in the laser intensity range from 70 mW/cm² up to 1.25 W/cm².

III. THEORETICAL MODEL

A. Outline of the model

In order to build a model of the nonlinear Hanle effect in Rb atoms in a cell, we will explore the concept of the density matrix of an atomic ensemble. The diagonal elements of the density matrix ρ_{ii} of an atomic ensemble describe the population of a certain atomic level i , and the non-diagonal elements ρ_{ij} describe coherences created between the levels i and j . In our particular case the level in question are magnetic sublevels of a certain HFS level. If atoms are excited from the ground state HFS level g to the excited state HFS level e , then the density matrix consists of elements $\rho_{g_i g_j}$ and $\rho_{e_i e_j}$, called Zeeman coherences, as well as "cross-elements" $\rho_{g_i e_j}$, called optical coherences.

The optical Bloch equations (OBEs) can be written as [9]:

$$i\hbar \frac{\partial \rho}{\partial t} = [\hat{H}, \rho] + i\hbar \hat{R}\rho, \quad (1)$$

where the operator $\hat{R}$ represents the relaxation matrix. If an atom interacts with laser light and an external dc magnetic field, we can write the Hamiltonian $\hat{H} = \hat{H}_0 + \hat{H}_B + \hat{V}$. $\hat{H}_0$ is the unperturbed atomic Hamiltonian, which depends on the internal atomic coordinates, $\hat{H}_B$ is the Hamiltonian of the atomic interaction with the magnetic field, and $\hat{V} = -\hat{\mathbf{d}} \cdot \mathbf{E}(t)$, the dipole interaction operator, where $\hat{\mathbf{d}}$ is the electric dipole operator and $\mathbf{E}(t)$, the electric field of the excitation light.

To use the OBEs to describe the interaction of alkali atoms with laser radiation in the presence of a dc magnetic field, we describe the light classically as a time dependent electric field of a definite polarization $\mathbf{e}$:

$$\mathbf{E}(t) = \varepsilon(t) \mathbf{e} + \varepsilon^*(t) \mathbf{e}^* \quad (2)$$

$$\varepsilon(t) = |\varepsilon_{\bar{\omega}}| e^{-i\Phi(t) - i(\bar{\omega} - \mathbf{k}_{\bar{\omega}} \cdot \mathbf{v})t}, \quad (3)$$

where $\bar{\omega}$ is the center frequency of the spectrum and $\Phi(t)$ is the fluctuating phase, which gives the spectrum a finite bandwidth $\Delta\omega$. In this model the line shape of the exciting light is Lorentzian with line-width $\Delta\omega$. The atoms move with a definite velocity $\mathbf{v}$, which causes the shift $\bar{\omega} - \mathbf{k}_{\bar{\omega}} \cdot \mathbf{v}$ in the laser frequency due to the Doppler effect, where $\mathbf{k}_{\bar{\omega}}$ is the wave vector of the excitation light.

The dipole matrix element that couples the i sublevel with the j sublevel can be written as: $d_{ij} = \langle i | \mathbf{d} \cdot \mathbf{e} | j \rangle$. In the external magnetic field, sublevels are mixed so that each sublevel i with magnetic quantum number M and other quantum numbers labeled as ξ is mixture of different hyperfine states $|F M\rangle$ with mixing coefficients $C_{i,F,M}$:

$$|i\rangle = |\xi M\rangle = \sum_F C_{i,F,M} |F M\rangle \quad (4)$$

The mixing coefficients $C_{i,F,M}$ are obtained as the eigenvectors of the Hamiltonian matrix of a fine structure state in the external magnetic field.

The dipole transition matrix elements $\langle F_k M_k | \mathbf{d} \cdot \mathbf{e} | F_l M_l \rangle$ should be expanded further using angular momentum algebra, including the Wigner – Eckart theorem and the fact that the dipole operator acts only on the electronic part of the hyperfine state, which consists of electronic and nuclear angular momentum (see, for example, [15]).

B. Rate equations

The rate equations for Zeeman coherences are developed by applying the rotating wave approximation to the optical Bloch equations, using an adiabatic elimination procedure for the optical coherences [9], and then accounting realistically for the fluctuating laser radiation by taking statistical averages over the fluctuating light field phase (*the decorrelation approximation*), and assuming a specific phase fluctuation model – random phase jumps or continuous random phase diffusion. As a result we arrive at the rate equations for Zeeman coherences for the ground and excited state sublevels of atoms [10]. In applying this approach to a case in which atoms are excited only in the finite region corresponding to the laser beam diameter we have to take into account transit relaxation. Then we obtain the following result:

$$\begin{aligned}
\frac{\partial \rho_{g_i g_j}}{\partial t} &= -i\omega_{g_i g_j} \rho_{g_i g_j} - \gamma \rho_{g_i g_j} + \sum_{e_i e_j} \Gamma_{g_i g_j}^{e_i e_j} \rho_{e_i e_j} + \lambda \delta(g_i, g_j) \\
&+ \frac{|\varepsilon \bar{\omega}|^2}{\hbar^2} \sum_{e_k, e_m} \left(\frac{1}{\Gamma_R + i\Delta_{e_m g_i}} + \frac{1}{\Gamma_R - i\Delta_{e_k g_j}} \right) d_{g_i e_k}^* d_{e_m g_j} \rho_{e_k e_m} \\
&- \frac{|\varepsilon \bar{\omega}|^2}{\hbar^2} \sum_{e_k, g_m} \left(\frac{1}{\Gamma_R - i\Delta_{e_k g_j}} d_{g_i e_k}^* d_{e_k g_m} \rho_{g_m g_j} + \frac{1}{\Gamma_R + i\Delta_{e_k g_i}} d_{g_m e_k}^* d_{e_k g_j} \rho_{g_i g_m} \right)
\end{aligned} \tag{5}$$

$$\begin{aligned}
\frac{\partial \rho_{e_i e_j}}{\partial t} &= -i\omega_{e_i e_j} \rho_{e_i e_j} - \gamma \rho_{e_i e_j} - \Gamma \rho_{e_i e_j} \\
&+ \frac{|\varepsilon \bar{\omega}|^2}{\hbar^2} \sum_{g_k, g_m} \left(\frac{1}{\Gamma_R - i\Delta_{e_i g_m}} + \frac{1}{\Gamma_R + i\Delta_{e_j g_k}} \right) d_{e_i g_k} d_{g_m e_j}^* \rho_{g_k g_m} \\
&- \frac{|\varepsilon \bar{\omega}|^2}{\hbar^2} \sum_{g_k, e_m} \left(\frac{1}{\Gamma_R + i\Delta_{e_j g_k}} d_{e_i g_k} d_{g_k e_m}^* \rho_{e_m e_j} + \frac{1}{\Gamma_R - i\Delta_{e_i g_k}} d_{e_m g_k} d_{g_k e_j}^* \rho_{e_i e_m} \right),
\end{aligned} \tag{6}$$

where g_i denotes the ground state magnetic sublevel, e_j denotes the excited state sublevel, $\omega_{ij} = (E_i - E_j)/\hbar$, $d_{e_i g_j} = \langle e_i | \mathbf{d} \cdot \mathbf{e} | g_j \rangle$ is the transition dipole matrix element,

$$\Delta_{ij} = \bar{\omega} - \mathbf{k}_{\bar{\omega}} \mathbf{v} - \omega_{ij}, \tag{7}$$

$\Gamma_R = \frac{\Gamma}{2} + \frac{\Delta \omega}{2} + \gamma$, Γ is the relaxation rate of the excited level, γ is the transit relaxation rate, and λ is the transit relaxation rate at which "fresh" atoms move into the interaction region. The rate λ at which atoms are supplied into the interaction region can be estimated as $1/(2\pi\tau)$, where τ is time in which atom crosses the laser beam due to thermal motion at a velocity v . It is assumed that the atomic equilibrium density outside the interaction region is normalized to 1, which leads to $\lambda = \gamma$. $\Gamma_{g_i g_j}^{e_i e_j}$ is the rate at which excited state coherences are transferred to the ground state as a result of spontaneous transitions [15]. If the system is closed, all excited state atoms in spontaneous transition return to the initial state, $\sum_{g_i g_j} \Gamma_{g_i g_j}^{e_i e_j} = \Gamma$.

We look at quasi stationary excitation conditions so that $\partial \rho_{g_i g_j} / \partial t = \partial \rho_{e_i e_j} / \partial t = 0$. In (5) the first term on the right-hand-side of the equation describes the destruction of the ground state Zeeman coherences due to magnetic sublevel splitting in an external magnetic field. The second term characterizes the destruction of ground state density matrix due to transit relaxation. The next term shows the transfer of population and coherences from the excited state to the ground state due to spontaneous transitions. The fourth term describes how the population of "fresh atoms" is supplied to the initial state from the regions outside of the laser beam in a process of transit relaxation. The fifth term shows the influence of the induced transitions to the ground state density matrix. And finally, the last term describes the change of

the ground state density matrix in the process of light absorption.

The terms in the equations for the excited state density matrix, Eq. (6), can be described in a similar way. The first term shows the destruction of Zeeman coherences by the external magnetic field. The second term shows transit relaxation. The third term is responsible for the spontaneous decay of the state. The fourth term shows the influence of the induced transitions on the density matrix of the excited state.

For a multilevel system interacting with laser radiation, we can define the effective Rabi frequency in the form $\Omega = \frac{|\varepsilon \bar{\omega}|}{\hbar} \langle J_e \| d \| J_g \rangle$, where J_e is the angular momentum of the excited state fine structure level and J_g is the angular momentum of the ground state fine structure level. The influence of the magnetic field appears directly in the magnetic sublevel splitting ω_{ij} and indirectly in the mixing coefficients C_{i, F_k, M_i} and C_{j, F_l, M_j} of the dipole matrix elements d_{ij} .

By solving the rate equations as an algebraic system of linear equations for $\rho_{g_i g_j}$ and $\rho_{e_i e_j}$ we get the density matrix of the excited state. This matrix allows us to obtain immediately the intensity of the fluorescence characterized by the polarization vector $\tilde{\mathbf{e}}$ [15]:

$$I(\tilde{\mathbf{e}}) = \tilde{I}_0 \sum_{f_i, e_i, e_j} d_{f_i e_j}^{(ob)*} d_{e_i f_i}^{(ob)} \rho_{e_i e_j}, \tag{8}$$

where $\tilde{I}_0$ is a proportionality coefficient. The dipole transition matrix elements $d_{e_i f_j}^{(ob)} = \langle e_i | \mathbf{d} \cdot \tilde{\mathbf{e}} | f_j \rangle$ characterize the dipole transition from the excited state e_i to some final state f_j for the transition on which the fluorescence is observed.

When we want to get the formula for the fluorescence which is produced by an ensemble of atoms, we have to average the previously written expression for the fluorescence over the Doppler profile $I(\mathbf{\bar{e}}) = I(\mathbf{\bar{e}}, \mathbf{k}_{\bar{\omega}} \mathbf{v}, B)$, taking into account different velocity groups $\mathbf{k}_{\bar{\omega}} \mathbf{v}$. If the total fluorescence without discrimination of the polarization or frequency is recorded, one needs to sum the fluorescence over all the polarization components and all possible final state HFS levels.

C. Theoretical results

Our model was used to analyze experimental data obtained for atoms excited with circularly polarized light at a geometry shown in Fig. 2.

In the experiment, atoms are excited at the resonance D_2 line on the fine structure transition $5S_{1/2} \longleftrightarrow 5P_{3/2}$. The fine structure states are split and form the manifold of hyperfine levels corresponding to nuclear spin $I = 5/2$ and $3/2$ for ^{85}Rb and ^{87}Rb respectively. The hyperfine constants for these levels can be found in [16]. In the signal simulation, the following numerical values of the parameters related to the experiment conditions were used: $\Gamma = 6$ MHz, $\gamma = 0.01$ MHz, $\Delta\omega = 15$ MHz, $\Delta\nu_D = 500$ MHz. We found that the model reproduces the measured signals reasonably well for all frequencies of the excitation laser including excitation rather far from the maximal absorption frequency.

The total intensity of the fluorescence was simulated without selecting the frequency or polarization, as was done in the measurement. For the theoretical simulation we also assume that the laser frequency does not change significantly during one magnetic field scan.

In the calculation we found that the Rabi frequency $\Omega = 250$ MHz gives the best fit of experimental measurements obtained at the laser light intensity $W = 1250$ mW/cm².

The first set of data we analyzed was the dependance of the fluorescence intensity on the external magnetic field B strength for different excitation laser frequencies $\bar{\omega}$. In Fig. 4 the dependance of the experimental and simulated fluorescence signal on the magnetic field strength is plotted for different laser frequencies in the region of excitation from the $F_g=3$ hyperfine level of ^{85}Rb (see Fig.3). In case (a) it was assumed that the laser frequency $\bar{\omega}$ corresponds to the frequency ω_{34} of the HFS cycling transition $F_g = 3 \rightarrow F_e = 4$ of an atom at rest when there is no magnetic field. In case (b) $\bar{\omega} = \omega_{34} - 625$ MHz, which corresponds to the laser frequency to the left of the main peak of the fluorescence excitation spectrum (see Fig. 3). In case (c) $\bar{\omega} = \omega_{34} + 390$ MHz, which corresponds to the laser frequency to the right of the main fluorescence peak.

The second set of the data we analyzed (see Fig. 5) was dependance of the fluorescence on the external magnetic

field B when we are observing the excitation from the ^{85}Rb ground state hyperfine level $F_g = 2$ (see Fig. 3). In case (a) the laser frequency was $\bar{\omega} = \omega_{34} + 2646$ MHz, for case(b) it was $\bar{\omega} = \omega_{34} + 2793$ MHz, and for case (c) $\bar{\omega} = \omega_{34} + 2935$ MHz.

The third set of data we analyzed was the dependance of the fluorescence on the external magnetic field B for different laser light intensities. We chose to use a B -field scan that corresponded to the laser frequency $\bar{\omega} = \omega_{34}$. Since the intensity of the laser light should be proportional to Ω^2 (see, for example, [17]), and since it was found from our simulation that for $I = 1250$ mW/cm², the corresponding value of the Rabi frequency is $\Omega = 250$ MHz, it can be expected that for the laser intensities $I = 900, 330,$ and 70 mW/cm², which were also used in the experiment, the values of the corresponding Rabi frequencies should be $\Omega = 215, 130,$ and 60 MHz, respectively. The results of the comparison of the measured signals with the simulated curves are presented in Fig. 6.

IV. ANALYSIS AND DISCUSSION

In our theoretical simulations as well as in the experimental results, we see qualitatively different changes in the fluorescence intensity for different excitation frequencies when the magnetic field is scanned. For some excitation frequencies the peaks in the vicinity of zero magnetic field are observed, while for other excitation frequencies dips are observed instead. In particular, in the case when excitation occurs from the ground state HFS level $F_g = 3$ of ^{85}Rb (see Fig. 4), we see a peak at $B = 0$. This dip is called a *bright resonance*. It typically occurs when the excitation scheme $F_g \rightarrow F_e = F_g + 1$ is executed. A detailed explanation of the mechanisms that lead to the formation of bright resonances is given in [5, 18, 19].

To use this mechanism to explain the peaks in the signals simulated and measured for excitation of ^{85}Rb atoms from the $F_g = 3$ and ^{87}Rb atoms from the $F_g = 2$ ground state HFS levels we have to demonstrate that the respective transitions $F_g = 3 \rightarrow F_e = 4$ and $F_g = 2 \rightarrow F_e = 3$ give the main contribution to the fluorescence signal.

Let us perform this analysis for the absorption from the $F_g = 3$ state to excited state levels $F_e = 2, 3, 4$ of ^{85}Rb . In the present experimental conditions, we can spectrally resolve ground-state HFS levels of Rb and cannot resolve excited-state HFS levels. Two points are important to understand the formation of these bright resonances. First, for this excitation scheme the laser line-width (15 MHz) is small in comparison to the mean energy separation (around 100 MHz) between excited state HFS levels. As a result, we can assume that different atoms in

FIG. 4: Dependence of the fluorescence signal on the magnetic field when the laser light frequency $\bar{\omega}$ is adjusted to the transition ω_{34} (a), when $\bar{\omega} = \omega_{34} - 625\text{MHz}$ (b), and when $\bar{\omega} = \omega_{34} + 390\text{MHz}$ (c). The thin line represents the theoretical simulation.

FIG. 5: Dependence of the fluorescence signal on the magnetic field when laser the frequency of the laser light $\bar{\omega}$ is adjusted to the transition $\bar{\omega} = \omega_{34} + 2646\text{MHz}$ (a), when $\bar{\omega} = \omega_{34} - 2793\text{MHz}$ (b) and when $\bar{\omega} = \omega_{34} + 2935\text{MHz}$ (c). The thin line represents the theoretical simulation.

FIG. 6: Dependence of the fluorescence signal on the magnetic field when the mean frequency of the laser light $\bar{\omega} = \omega_{34}$ and the intensity I of the laser light is: (a) $I = 1250\text{ mW/cm}^2$ ($\Omega = 250\text{ MHz}$); (b) $I = 900\text{ mW/cm}^2$ ($\Omega = 215\text{ MHz}$); (c) $I = 330\text{ mW/cm}^2$ ($\Omega = 130\text{ MHz}$); (d) $I = 70\text{ mW/cm}^2$ ($\Omega = 60\text{ MHz}$). The thin line represents the theoretical simulation.

different velocity groups interact with laser light independently. Besides taking into account the Doppler contour width (around 500 MHz), we can assume that for a rather large detuning of the laser frequency from the exact resonance of any of the transitions $F_g = 3 \rightarrow F_e = 2, 3, 4$, there still will be atoms in some velocity group that will be in resonance with the laser excitation as a result of the Doppler shift.

Secondly, the ground state HFS levels for ^{85}Rb have quantum numbers $F_g = 2, 3$. The excited $P_{3/2}$ state has HFS levels with quantum numbers $F_e = 1, 2, 3, 4$. For the transitions that start from the spectrally resolved ground-state level $F_g = 3$ only the transition $F_g = 3 \rightarrow F_e = 4$ is closed (cycling). This means that atoms after the absorption of a photon can return only to the initial ground-state level $F_g = 3$ and cannot go to the other ground-state level $F_g = 2$, which does not interact with the laser light. The consequence of this situation is that after several absorption and fluorescence cycles, all atoms will be optically pumped to the $F_g = 2$ level, except atoms with the velocity group that corresponds to the resonance with closed $F_g = 3 \rightarrow F_e = 4$ transition. This transition exhibits a bright resonance in the magnetic field. This is the reason why in the experiment, even when the laser radiation is detuned from the exact $F_g = 3 \rightarrow F_e = 4$ resonance to the resonance with open transitions for the atom at rest, we still observe bright resonances. This qualitative explanation of the mechanism of resonance formation is supported by the solution of the exact model.

In the case when excitation occurs for ^{85}Rb from the ground-state HFS level $F_g = 2$ (see Fig. 5) we observe dips in the vicinity of $B = 0$. This dip is called a *dark*

resonance. It typically occurs when the excitation scheme is $F_g \rightarrow F_e = F_g - 1$ [5, 18, 19]. For the excitation from the ground state HFS level $F_g = 2$ in ^{85}Rb the only closed transition is $F_g = 2 \rightarrow F_e = 1$. Similar to the previous case, one can argue that the dark resonances when atoms are excited from the $F_g = 2$ in ^{85}Rb should be attributed to this transition at any laser frequency within the Doppler profile.

V. CONCLUDING REMARKS

In summary, we can conclude that the double scanning technique is a powerful tool to study simultaneously frequency and magnetic field dependence of nonlinear zero field level-crossing signals, the nonlinear Hanle effect. In this report we wanted to draw attention to the extended possibilities offered by this technique. Together with the improved model of the magneto-optical processes it allows efficient measurements of these signals and provides a rather detailed theoretical description of the signals that reproduces experimentally measured signals with high accuracy.
